1.0 INTRODUCTION

This report describes the calibration methods and steps employed to develop flow-habitat relationships using one-dimensional (1D) modeling in the Redwood Creek watershed (Figure 1). The completed hydraulic models were later combined with juvenile salmonid habitat suitability criteria (HSC) to estimate habitat availability, expressed as area-weighted habitat suitability (AWS), available to the species and life stages present in the watershed over a range of flows.

In 2016, the California Department of Fish and Wildlife (Department) implemented an instream flow study in mainstem Redwood Creek and five of its major tributaries including Seely, Somerville, Miller, Upper Redwood, and China creeks. Department staff performed 1D modeling following standard procedures developed by the Department, U.S. Geological Survey (USGS), and U.S. Fish and Wildlife Service.

Information typically required to develop flow-habitat relationships using the 1D modeling approach include, but are not limited to:

- Mesohabitat type mapping and inventory;
- Transect selection;
- Transect surveys at three distinct flows on the descending limb of the hydrograph;
- Calibration flow selection;
- Hydraulic model utility selection;
- Hydraulic model calibration by application of performance standards;
- Selection of HSC or development of site-specific HSC;
- Computation of AWS by species and life stage; and
- Habitat time series development to recommend flows by month and water year type.

This report presents the results of the mesohabitat mapping and inventory for Redwood Creek and its tributaries, transect selection, field methods used to collect the data for the hydraulic model, hydraulic model utility selection, and the hydraulic model calibration results. Site-specific HSC were developed for the South Fork Eel River watershed and appear in a companion report, *Habitat Suitability Criteria for Juvenile Salmonids in the South Fork Eel River Watershed, Mendocino and Humboldt Counties* (Gephart et al. 2020). The results of the HSC report and this report will be combined to estimate AWS for the species and life stages present in Redwood Creek, in a third report: *Instream Flow Evaluation: Juvenile Steelhead and Coho Salmon Rearing in Redwood Creek, Humboldt County* (Maher et al. in prep). The scope of this report is

limited to presenting the data required to perform the 1D hydraulic modeling and model calibration.

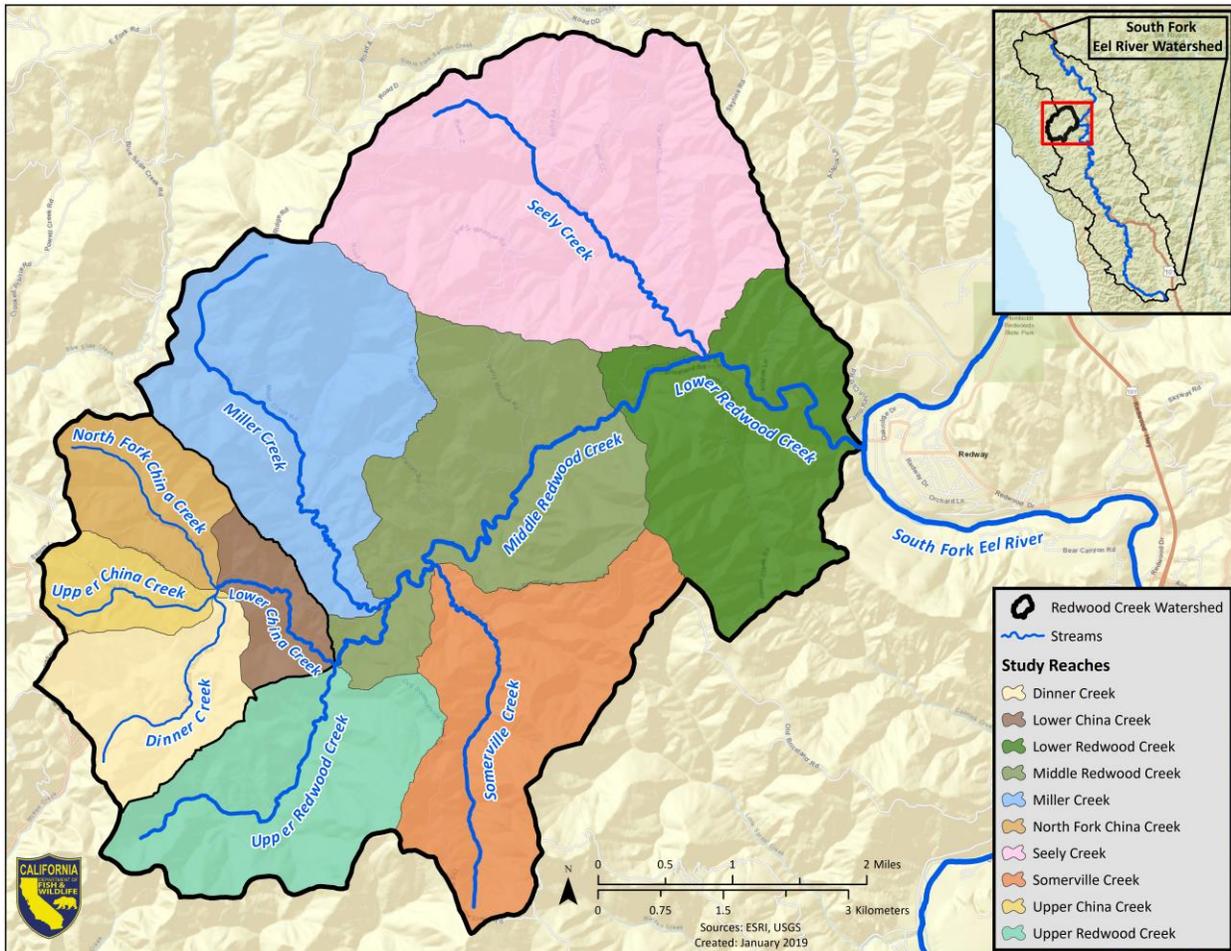

Figure 1. Redwood Creek study reaches within the South Fork Eel River watershed.

2.0 METHODS

The Department uses the Instream Flow Incremental Methodology (IFIM) to conduct aquatic instream flow evaluations in California's streams and rivers (CDFG 2008). IFIM is a comprehensive and incremental framework used to guide instream flow evaluations and associated decision-making processes. The 1D method, developed by the U.S. Fish and Wildlife Service Instream Flow Group (Milhous et al. 1989), is one assessment tool available within the suite of IFIM methodologies. The 1D method can be used to simulate a relationship between streamflow and physical habitat for various life stages of a species of fish. The method includes three major components: river hydraulics, species life stage microhabitat suitability, and physical habitat modeling.

One-dimensional modeling was selected to determine the relationship between streamflow and hydraulic habitat for rearing juvenile salmonids in Redwood Creek. The 1D method is typically performed using a computer software program that integrates the three modeling components (i.e., river hydraulics, species life stage microhabitat suitability, and physical habitat modeling) together. The Department selected the commercially available program System for Environmental Flow Analysis (SEFA; Jowett et al. 2014) to perform 1D modeling in the Redwood Creek watershed. The development and implementation of an instream flow study using 1D modeling contains numerous steps (Figure 2) as were followed in the current study. This report describes steps shown in green (“Hydraulic Data Collection and Modeling”). The other steps are described in the companion report, *Instream Flow Evaluation: Juvenile Steelhead and Coho Salmon Rearing in Redwood Creek, Humboldt County* (Maher et al. in prep).

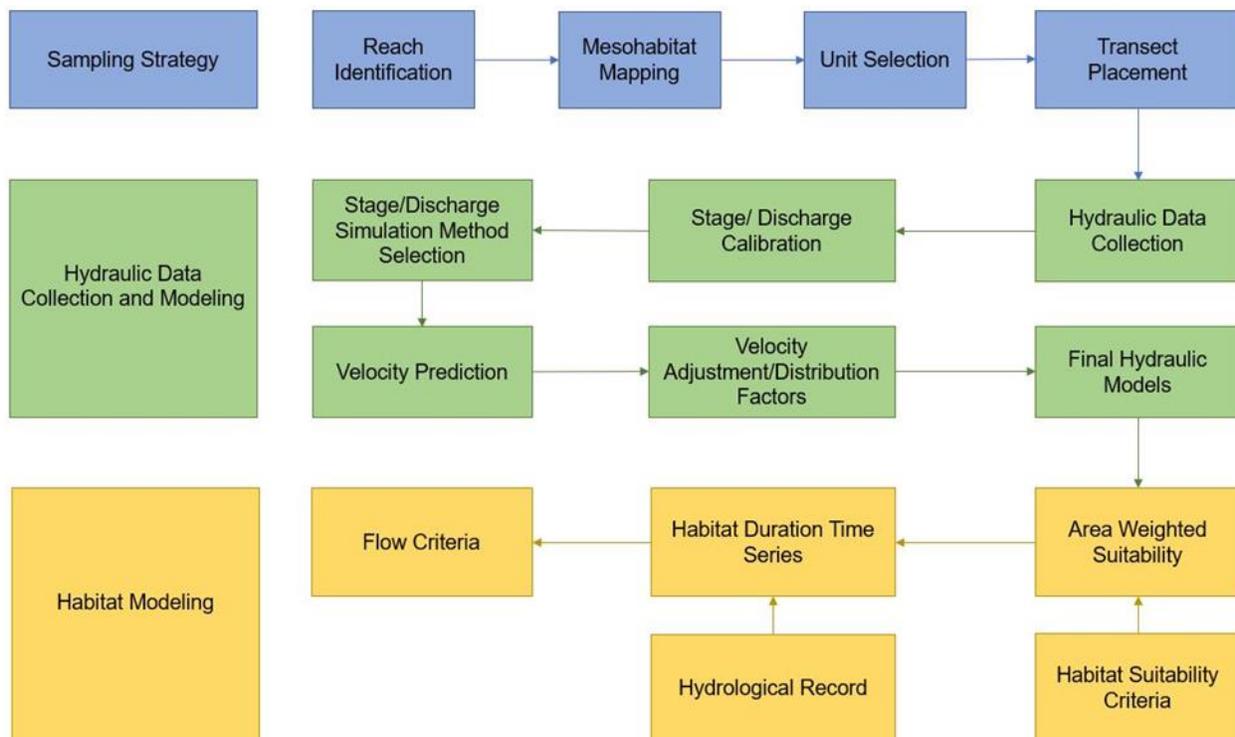

Figure 2. Workflow chart for Redwood Creek instream flow models.

2.1 Mesohabitat Mapping and Transect Selection

The Redwood Creek watershed was divided into 10 reaches representing homogeneous stream segments (see Figure 1 and Maher et al. in prep for more details). A mesohabitat mapping survey was performed throughout each reach. The survey was conducted intermittently between December 2015 and April 2016, dependent on precipitation events and safe wading conditions. Hydraulic model relationships are sensitive to lateral and longitudinal changes in the streambed profile.

Lateral changes affect the relative relationship between water surface elevation (WSEL) measured along a transect line at different points in time. Longitudinal changes affect transects where the slope of the hydraulic gradient is a function of a downstream hydraulic control point, typically pool units. Obtaining the necessary range of water stage/discharge pairs proved challenging in Redwood Creek. Spring storms delayed the start of data collection due to exceedingly high flows and subsequent safety concerns. Once the spring storms had subsided, flows quickly receded due to pressure from competing land uses. To widen the range of flows sampled, staff attempted to obtain late fall stage and discharge measurements once rainfall returned to the watershed and flow volumes increased. The attempt to measure higher water stage and discharge was successful in some of the reaches, but in others, earlier fall storms had altered several previously sampled streambed profiles. In these circumstances, the late fall data could not be used as they did not compare with the previously surveyed streambed profile. Some transects were omitted due to lack of high flow measurements.

Initially, 105 randomly located transects were selected for 1D hydraulic model simulation (Table 1 to Table 10). However, a total of 30 transects were eventually omitted from use in their respective reaches because the hydraulic model outputs did not meet existing performance standards provided in the literature (Milhous et al. 1989; Thomas R. Payne and Associates 1998; USFWS 1994; USFWS 2011; USGS 2001). The final number of transects considered for the hydraulic model portion of the study was 75. Three transects were selected per mesohabitat type. Transects rejected through calibration are indicated by strikethrough and asterisks (*) in Table 1 through Table 10. A map of each reach is provided in Appendix A. The approximate location of each transect is shown in each reach map.

2.2 Hydraulic Model Data Collection

Hydraulic data collection procedures were consistent with pre-established standards and protocols intended to characterize the hydraulic habitat potential in each representative mesohabitat unit type (Bovee 1997; CDFW 2013b). The data required for use in 1D modeling were collected at three distinct flow regimes referred to here as the Low, Mid, and High Flows. Sample flows were targeted using the 80, 50, and 20 percent exceedance flows for mainstem Redwood Creek. A long-term hydrologic record does not exist for Redwood Creek. A relatively unimpaired, long term stream gage record was available from Bull Creek, a nearby watershed with comparable hydrologic properties (Cowan 2018). The Bull Creek stream gage record was scaled to estimate Low, Mid, and High Flow regime exceedance flows of 3, 19, and 126 cubic feet per second (cfs), respectively, for mainstem Redwood Creek.

Data collection was scheduled to coincide as near as possible to predetermined target flows intended to capture the range of flows frequently experienced within the Redwood Creek watershed. Hydraulic data were collected along the descending limb of the hydrograph from March through June of 2016. Staff returned to some sites in November and December of 2016 to capture an adequate range of flows.

The streambed profile, substrate, and cover coding for each transect were surveyed during the first data collection event, typically the High Flow survey. WSEL was recorded and discharge was measured at each survey event. The velocity profile was generally recorded during the Mid Flow survey, but seasonal fluctuations in flow led to

the occasional velocity profile collection at the High Flow survey. Stage of zero flow (SZF) measurements were collected at Low Flow (Table 11).

Table 11. Data collected for target flow regimes used in 1D modeling.

Flow Regime	Streambed Profile, Substrate, & Cover	WSEL/ Discharge	Velocity Profile	SZF
High	Collected	Collected	Collected	-
Mid	-	Collected	Collected	-
Low	-	Collected	-	Collected

2.2.1 Streambed Profile Surveys, WSEL, and Vertical Controls

To provide a complete elevational bed profile, steel rebar were set at the ends of each transect, establishing a head pin and tail pin. An upstream facing convention was used to establish the position of the head pin on the left bank and the tail pin on the right bank. Fiberglass measuring tapes were hooked to the head pins and wrapped around the tail pins during each survey to demarcate transect stations for velocity profiles and elevation surveys (Bovee 1997). Surveys were performed using standard differential survey methods consistent with the Department’s *Standard Operating Procedure for Streambed and Water Surface Elevation Data Collection in California* (CDFW 2013b). Streambed elevation measurements were collected at one-foot intervals along the transect using a stadia rod and an auto level fixed to a tripod. Vertical control was maintained at each unit by a vertical benchmark, consisting of lag bolts typically pounded into mature tree roots or trunks (Figure 3). All streambed elevations and WSELs were measured using a Nikon AE-7 automatic level and stadia rod (Figure 4). WSELs were measured at a minimum of three significantly different stream discharges to the nearest 0.01 feet (ft). Staff gages were installed at each unit to monitor change in stage during the course of WSEL, velocity, and discharge data collection. Staff gages were graduated and read to the nearest 0.01 ft.

One-dimensional modeling assumes the WSEL at each transect is of constant elevation. One representative WSEL must be chosen from the measurements recorded during each WSEL transect survey. The user’s manual for 1D modeling (USGS 2001) provides the following guidance to select a representative WSEL based on levels of variance in the measurements as follows:

The difference between the measured right and left bank water surface elevations can vary considerably with differences of 0.1 to 0.5 ft occurring in highly turbulent conditions. The analyst should select the average of the left bank and the right bank, only left or only right bank, or other water surface elevation at each cross section in the regression equations based on the conditions reported in the field notes.

A minimum of three WSELs were recorded along each transect. One measurement was taken near each bank and another near the middle of the channel. Typically, the water surface was flat and WSELs did not vary by more than 0.05 ft. The mean was taken for WSELs within this range generating a single representative WSEL. In some instances where the water surface was varied, more measurements were recorded to accurately depict changes in water surface height. Where WSELs ranged between 0.05 and 0.1 ft, each transect was evaluated to determine if any of the WSEL measurements recorded were not representative of the water surface surveyed because of turbulent surface conditions or physical obstructions like large substrates at isolated areas along the transect line. Where the range in WSEL exceeded 0.1 ft, transects were evaluated in detail by reviewing field notes, schematic diagrams, and digital images to understand potential causes of variance. Specific WSEL measurements that appeared to be impacted by the conditions described above were excluded from computation of the mean WSEL.

In mesohabitat units with a downstream control point, typically pool units, the elevation of that control point represents the SZF (Figure 5). At that flow stage, all surface flow will be blocked by the control point. Locating the SZF can be difficult and is best found at the lowest flow surveyed (USGS 2001). As a result, the SZF for each pool unit was surveyed during the Low Flow event. The recorded SZF was later entered into SEFA for WSEL and discharge calibration.

Figure 3. Vertical benchmark driven into the base of tree trunk marked with flagging tape in foreground, and auto level in background.

Figure 4. Measuring WSEL and velocity along transect LRT62 in Lower Redwood Creek reach.

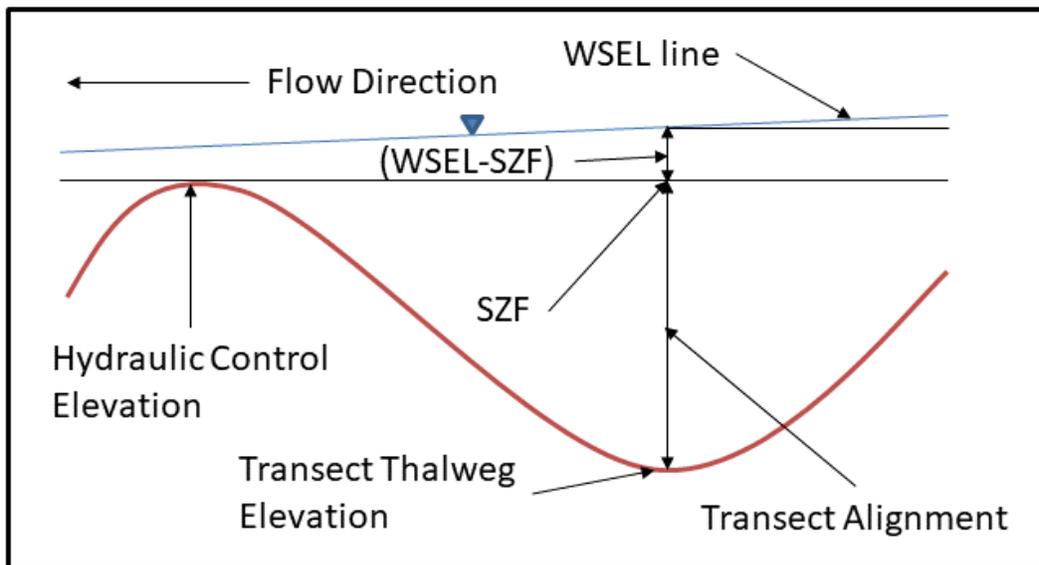

Figure 5. Stage of zero flow diagram.

2.2.2 Discharge

Discharge measurements were collected for each WSEL survey event at each distinct flow (either Low, Mid, or High) near the corresponding transect being surveyed. Discharge surveys were consistent with the Department's *Standard Operating Procedure for Discharge Measurements in Wadeable Streams in California* (Discharge

SOP; CDFW 2013a). A single discharge measurement could be used to represent the flow for multiple transects when transects were in close proximity to one another and where there were no flow inputs or diversions between transects. If necessary, multiple discharge measurements were taken within a given reach to account for additional flow inputs or diversions.

Discharge sites were selected where the best hydraulic characteristics could be found in the stream reach near the transect(s). Ideal discharge transects are relatively wide, uniform, and shallow (Bovee 1997; Figure 6). In all transects surveyed for discharge, a minimum of 20 cells were sampled. In areas of greater depth, cells were sampled to maintain the percent of any one cell less than 5% of the volume of flow. A temporary staff gage was installed during each discharge measurement (CDFW 2013a). The depth of the staff gage was read before and after each discharge to ensure the stream stage remained constant during the measurement.

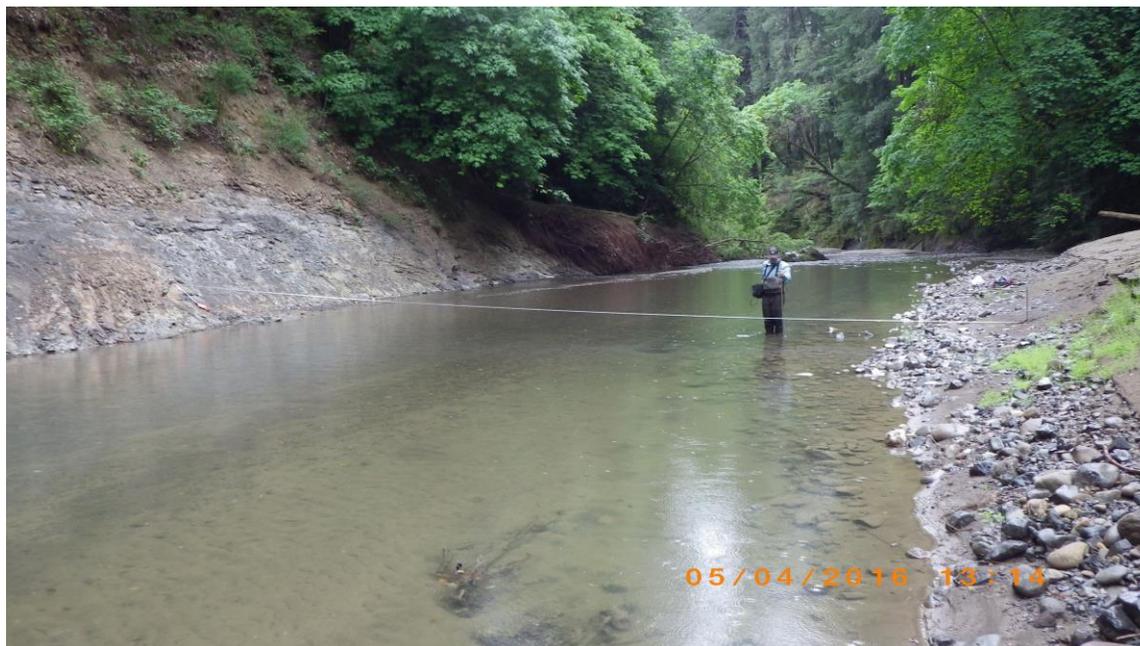

Figure 6. Discharge measurement in the Lower Redwood Creek reach.

2.2.3 Water Depth and Velocity

Bed elevations and velocity measurements were collected along each transect at one-foot increments across each transect at either the High or the Mid Flow event. Water depth was later calculated in SEFA by subtracting the surveyed bed profile elevations from the representative WSEL. The resulting velocity profile was used to simulate depth and velocity in SEFA. In SEFA, the transect survey when the velocity profile is measured is defined as the Survey Flow.

Velocities were measured using a Marsh-McBirney Flowmate Model 2000 or Hach FH950 velocity meter. Velocity meters were calibrated and used in accordance with the Discharge SOP (CDFW 2013a). The meters measured velocity in the water column to the nearest 0.01 feet per second (ft/s). For depths less than 2.5 ft, one velocity measurement was made at 0.6 of the total depth as measured down from the water's surface. Where the water depth was equal to or exceeded 2.5 ft, two velocity measures were collected and the mean of these two velocities was calculated; one at 0.2 and another at 0.8 of the total depth measured down from the water surface.

2.2.4 Substrate and Cover Classifications

Substrate and cover are additional attributes that can be used to estimate AWS, depending upon life stage. Substrate and cover data were collected concurrently at points selected for bed elevation measurements. All substrate data collected on the transects were assessed by one observer based on the visually estimated average of multiple particle sizes. Cover data were collected by visual observation of the presence and type of cover and proximity to the survey point. The codes used to classify substrate and cover are provided in Table 12 and Table 13, respectively.

Table 12. Substrate codes, descriptors, and particle sizes (USFWS 2011).

Code	Type	Particle Size (inches)
0.1	Sand/Silt	<0.1
1	Small gravel	0.1 – 1
1.2	Medium gravel	1 – 2
1.3	Medium/Large gravel	1 – 3
2.3	Large gravel	2 – 3

Log (>1' diameter)	5
Log + overhead	5.7
Overhead cover (>2' above substrate)	7
Undercut bank	8
Aquatic vegetation	9
Aquatic vegetation + overhead	9.7
Rip-rap	10

2.2.5 Data Quality Control

To ensure accuracy during data collection, equipment was calibrated according to the manufacturer's instructions. Details about field equipment calibration can be found in the Discharge SOP (CDFW 2013a).

Data including but not limited to flow velocity, water depths, substrate, cover, WSELs, and bed elevations were documented in the field on Rite in the Rain paper. Field data were checked for accuracy and completeness by the field crew leader at the end of each field day. Any incomplete data were corrected in the field on the data sheets. Photographs of each transect were taken during each survey to document site conditions. Schematic drawings were prepared of each transect on the WSEL data sheet, indicating the location of obstacles such as downed trees, cobble bars, and boulders that may have affected WSELs and/or flow velocities.

Department scientific staff transcribed numerical data into Excel workbooks upon return to the office. If any errors in the physical data sheets were identified during the transcription process, the error on the physical data sheet was marked by strikethrough, correction added, and each correction was initialed and dated by staff. After the data were entered electronically, a different Department scientific staff member reviewed the electronic data against the paper field data sheets to confirm the accuracy of the transcription. Any errors found by this second reviewer were corrected using the original datasheets. Staff logged data entry date, quality control check completion date, and any data omissions or corrections in a spreadsheet to ensure that all field data forms were electronically entered and checked. Once the electronic data were verified and paper

field forms were filed, the electronic forms were used in future analysis. All data generated by this project will be maintained in scanned field logbooks and/or data sheets, and electronic spreadsheet format. The Department will store all electronic data (including photographs, scanned datasheets, Excel workbooks, study plans, and report documents) on Department-maintained servers that are regularly backed up.

Some data were discarded after returning to the office due to data quality issues, such as discharge measurements that did not comply with standards outlined in the SOP (CDFW 2013a), WSEL measurements that exceeded the margin of error, and changes in the bed profile due to substrate movement. These issues were noted in a data collection data quality log and the data were excluded from future analysis. When necessary, staff returned to the field site to re-take the field measurements.

During data analysis, data copied from one spreadsheet to another or from a spreadsheet to the report were quality checked by the Department's scientific staff using the same method described above. When data were imported into SEFA, HydroCalc, and Excel for analysis, the staff member verified that correct and complete data had been used and that the proper output data were incorporated in the reports. To verify the habitat duration time series analysis, a second staff member re-created the entire analysis and results.

2.2.6 Model Limitations

The two limitations of Physical Habitat Simulation system (PHABSIM) are transect location and the range of flows that can be simulated. The hydraulic models in PHABSIM assume the water surface is level across each transect (USGS 2001); therefore, randomly selected transects located where the WSEL varies by more than 0.1 ft are assumed to not be acceptable for hydraulic modeling in PHABSIM (see Section 2.2.1). The WSEL-discharge rating relationship of transects located where the WSEL varies beyond 0.1 ft are more likely to fail to meet standards for mean error, measured versus predicted WSEL, and/or velocity adjustment factor (VAF). Randomly selected transects where the WSEL varied beyond 0.1 ft were resampled. Simulation flow range is described in detail in Section 2.3.5.

2.3 SEFA

The 1D method simulates the relationship between streamflow and physical habitat for fish by combining the results of hydraulic models with HSC to estimate AWS. The SEFA software program (Jowett et al. 2014) contains the suite of computer models developed by USGS (Milhous et al. 1989). The SEFA program was used to perform the 1D method computations for each study reach in Redwood Creek. Hydraulic model preparation,

calibration, and simulation in SEFA followed the standard procedures and guidance given in the PHABSIM user's manual (USGS 2001).

Hydraulic modeling in the 1D method generally consists of the following procedures:

- Rating curve development and calibration using stage-discharge pairs measured in the field;
- Predictive hydraulic model utility selection;
- Water surface elevation simulation;
- Velocity simulation; and
- Results validation using standard guidance criteria.

2.3.1 Hydraulic Data Preparation and SEFA Input

The verified electronic data were organized by reach and imported into SEFA directly from Excel. Before transect data was entered into SEFA, senior engineering staff review the input files prepared by staff. The data entered into SEFA for each transect included the streambed profile, paired WSEL and discharge data, SZF (if applicable), the velocity profile, and substrate and cover codes. The mesohabitat type was entered manually into SEFA for each transect and reach.

2.3.2 Calculation Preferences

The calculation options in SEFA are set in one main menu, Hydraulic Habitat Options. The traditional default 1D options were used unless the SEFA support information indicated user inputs should be processed using another available option. The only non-default option selected was to use Instream Flow Group Model #4 (IFG4) emulation for the rating curve development and velocity prediction. IFG4 emulation is the recommended method when the bed profile elevations are derived from differential level measurements as opposed to water depth measurements (Jowett et al. 2014). The options selected in the Hydraulic Habitat Options menu are summarized in Table 14.

Table 14. Summary of SEFA user settings selected.

Menu Item	Menu Sub-Item	Selected Setting
Cross section extrapolation	Vertical bank created if slope at section start or end is less than	0.05
Velocity distribution calculation method	N/A	Conveyance (traditional method)
Conveyance for WSP	N/A	Harmonic and/or arithmetic mean
Hydraulic rating roughness	N/A	Flow
Rating curve method	N/A	IFG4 emulation
Velocity prediction method	N/A	IFG4 emulation
Habitat calculations	Method of calculating combined suitability index	Multiplication of individual suitabilities

2.3.3 WSEL and Discharge Calibration

The program SEFA was used to develop rating curves from the paired WSEL and discharge measurements. Stage-discharge relationships are derived from rating curves developed for each transect (Figure 7). SEFA contains the three utilities for developing stage-discharge relationships: IFG4 referred herein as log-log regression; Manning’s stage-discharge using Manning’s n (MANSQ), and Water Surface Profile Model via step-back computation (WSP; Jowett et al. 2014).

Log-log regression uses three or more measured stage and discharge pairs, along with the SZF elevation, to develop a relationship between stage and discharge based on the following equation:

$$Q = A \times (WSEL - SZF)^{exp}$$

Where:

- Q = flow (cfs)
- A = regression coefficient
- WSEL = water surface elevation (ft)
- SZF = stage of zero flow (ft)
- exp = exponential regression coefficient

The above equation is converted to log-log format and a log-log linear relationship is fit to the data. In a habitat unit where the slope of the longitudinal water surface is determined by a downstream hydraulic control point, like a pool or deep run, the elevation of that downstream control point is the SZF. In SEFA, a SZF optimization utility called *Best SZF* solves for the best fit to the log-log linear relationship by varying the SZF. In SEFA, the *Best SZF* rating is automatically provided in the displayed ratings field (Figure 7) with MANSQ and log-log regression ratings.

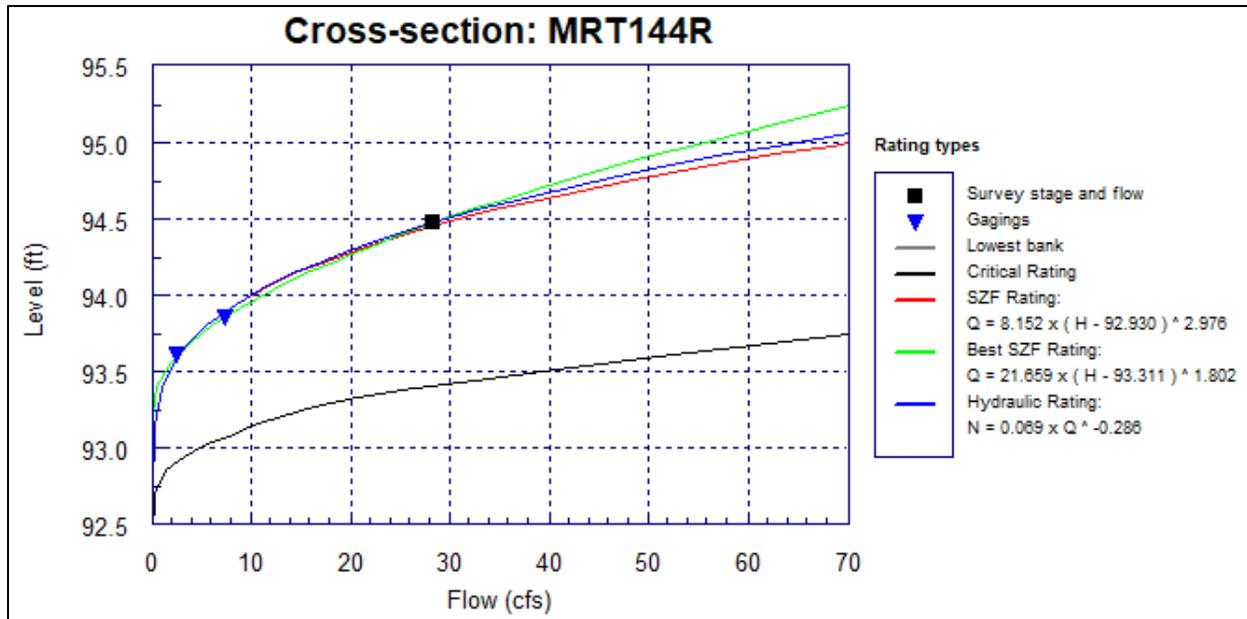

Figure 7. Example SEFA rating curve output.

In Figure 7, the red line is the SZF rating or log-log regression rating, the green line is the *Best SZF* Rating or log-log regression with a synthetic SZF that optimizes the log-log regression rating, the blue line is the Hydraulic Rating (MANSQ), the red line is the SZF Rating or log-log regression rating, the black line is the critical flow rating, the black square is the Survey stage used for velocity calibration, and the blue chevrons are the other stage-discharge pairs used to develop the ratings.

The critical flow rating refers to the rating curve derived so that the flow in the cross section is critical. SEFA uses Manning’s equation to solve for open channel flow, where the depth is assumed to be above the critical depth (Gupta 1995). The hydraulic utility MANSQ uses transect survey data and three or more measured stage and discharge pairs to develop a relationship between stage and discharge based on Manning’s equation as follows:

$$Q = 1/N \times Area \times (R - R_{SZF})^{2/3} \times S^{1/2}$$

Where:

Q = flow (cfs)

$N = A \times Q^{\text{beta}}$

A = regression coefficient

beta = MANSQ exponential regression coefficient

Area = cross sectional area of the transect (ft)

R = hydraulic radius

R_{SZF} = hydraulic radius at the SZF

S = slope of the water surface

The water surface profile model, WSP, calculates the energy loss between transects to determine WSELs. The use of WSP requires data from the transect of interest and one downstream transect, at least three stages at both transects, and the three corresponding flows to perform a step backwater calculation (similar to HEC-RAS) to develop the stage-discharge relationship. The data collection required to perform WSP was beyond the scope of this study and the method was not used.

Log-log regression and MANSQ were run on each transect, with MANSQ set as the default modeling method for transects where there was no clear downstream hydraulic control point. Log-log regression was used as the default modeling method for pool transects and for transects that did not calibrate well using MANSQ. The optimized *Best SZF* rating was used when field-based estimates of SZF were obscured from measurement by large boulders or wood substrates (see Section 4.0 *Discussion* for specific examples).

The default hydraulic utility MANSQ was selected to predict stage-discharge at all the transects except those with downstream hydraulic control points. MANSQ is based on the Manning's equation to solve for WSEL, whereas log-log is an empirical data regression. Log-log regression was used as the default modeling method for pool transects and for transects where the MANSQ mean error was 10% or greater. The optimized *Best SZF* rating was used when field-based estimates of SZF were obscured from measurement by large boulders or wood substrates.

Multiple references related to the use of 1D were consulted when developing a rationale for evaluating the calibration results of the stage-discharge rating utilities. These references included: *User's Guide to the Physical Habitat Simulation System (PHABSIM)* (Milhous et al. 1981); *Using the computer based physical habitat simulation system* (USFWS 1994); *PHABSIM for Windows: User's Manual and Exercises* (USGS 2001); and *User's Manual RHABSIM 3.0 Riverine Habitat Simulation Software for DOS and Windows* (Thomas R. Payne and Associates 1998).

The guidelines presented below were used when selecting the stage/discharge method for each transect.

- The mean error of predicted versus measured discharge does not exceed 10%;
- The maximum variance of any one predicted discharge compared to a measured discharge does not exceed 25%; and
- The difference between measured and predicted WSELs does not exceed 0.1 ft at a given calibration flow.

In addition, for MANSQ models, transects with beta values outside the range of 0 to 0.4 were evaluated further. For log-log regression models, the beta value must be within the range of 2.0 to 4.5. Preferred ranges of MANSQ beta vary amongst practitioners of instream flow studies. For example, the RHABSIM user's manual suggests 0 to 0.4 (Thomas R. Payne and Associates 1998) while the PHABSIM manual recommends 0 to 0.6 (USGS 2001).

Where MANSQ beta values exceeded 0.4, the senior engineering staff reviewed unit data to confirm stage/discharge results were not affected by errors in data collection or method application. Where predicted results for all the methods did not accurately predict measured values, staff reviewed field notes and digital images to understand potential causes for variance in predictive values versus field measurements.

Variance in discharge was assessed by reporting the VAF for each Survey Flow discharge. If the field velocities equal the simulated velocities at the Survey Flow, the VAF has an ideal value of 1.0. Based on recommended USFWS (1994) guidelines, a range of 0.75 to 1.25 was used to evaluate Survey Flow discharge VAFs.

2.3.4 Velocity Adjustment Factor Discharge Calibration

The survey flow (Q_{SF}) is the field discharge measurement associated with the selected velocity profile used to simulate velocities in SEFA. The VAF is the ratio between the survey flow and the discharge calculated in SEFA using the surveyed velocity profile.

$$VAF = Q_{SF}/Q_{SV}$$

For each transect, each velocity from the selected velocity profile is multiplied by the VAF such that $Q_{SV} = Q_{SF}$. A VAF can be used as one indicator of how well the transect velocity profile relates to the survey flow. The range of VAF factors used to calibrate flows for each transect should be 0.75 to 1.25 (Milhous et al. 1989). Transects with VAFs outside of the recommended range are omitted from further analysis.

2.3.5 Discharge Simulation Range

Extrapolation beyond the highest measured flow is often necessary to evaluate the possible range of flows needed by a species for activities such as spawning or

upstream passage. The range of discharge that can be simulated in 1D for a site while maintaining meaningful results is dependent on the characteristics of the transect including substrate size, hydraulic radius, bank geometry, and the presence of floodplains. Generally, to ensure extrapolated flows maintain their integrity, PHABSIM manuals have reported that 0.4 to 2.5 is an acceptable simulation range (USGS 2001), but more accurately, simulation range is limited by channel configuration, model performance, and data availability (USGS 2001).

2.3.6 Water Velocity Prediction

Velocities are simulated by multiplying the velocity profile collected during the survey flow by a range of VAF values. For velocity simulation, the recommended range of VAF factors should be 0.1 to 5.0 (TRPA 1998). SEFA computes velocity distribution factors (VDFs) from the velocity profile measured in the field at each transect (Jowett et al. 2014). A VDF is the ratio of the field measured velocities to the velocities calculated by SEFA using the transect VAF described above in the *Velocity Adjustment Factor Discharge Calibration* section. A VDF is used to modify the magnitude of individual transect cell velocities to improve the shape of the velocity profile simulation. The VDFs are automatically modulated by the SEFA program to improve the VAF. Note that SEFA refers to VDFs and Manning N values interchangeably.

Modifications to VDFs can be useful when small negative velocities caused by eddies occur along the transect near the stream margin. Eddies are typically caused by vegetation or large obstacles upstream of a transect (Figure 8). In SEFA, simulation velocity profiles are generated by multiplying the Survey Flow velocities by the VAF. A byproduct of this method is that the magnitude of small negative velocities become increasingly negative with higher simulated flows (Figure 9).

As the mid-column velocity depth rises with increased flow volume, the effect of bank vegetation and obstacles naturally dissipates or remains the same depending upon the severity of the vegetation or size of the upstream obstacle. In Figure 9, the small left side margin velocity increases in negative magnitude to over -2 ft/s at the high simulation flow. Adjustments were made to VDFs if the negative magnitude of a simulated cell velocity exceeded -1 ft/s or where the shape of the simulated velocity profile was not consistent with the surveyed velocity profile.

Modifications to VDFs are also useful when the shape of the simulated velocity profile contradicts the shape of the velocity profile measured in the field. For example, in Figure 10 the shape of the field velocity profile near stations 35 and 36 is inconsistent with the shape of the simulated velocity profile. The SEFA Software Manual (Jowett et al. 2014) recommends reviewing the field notes and reducing VDFs accordingly to improve the shape of the velocity profile.

Figure 8. Example of vegetation and obstacles near the stream margins causing velocity eddies. Lower Redwood Creek reach transect.

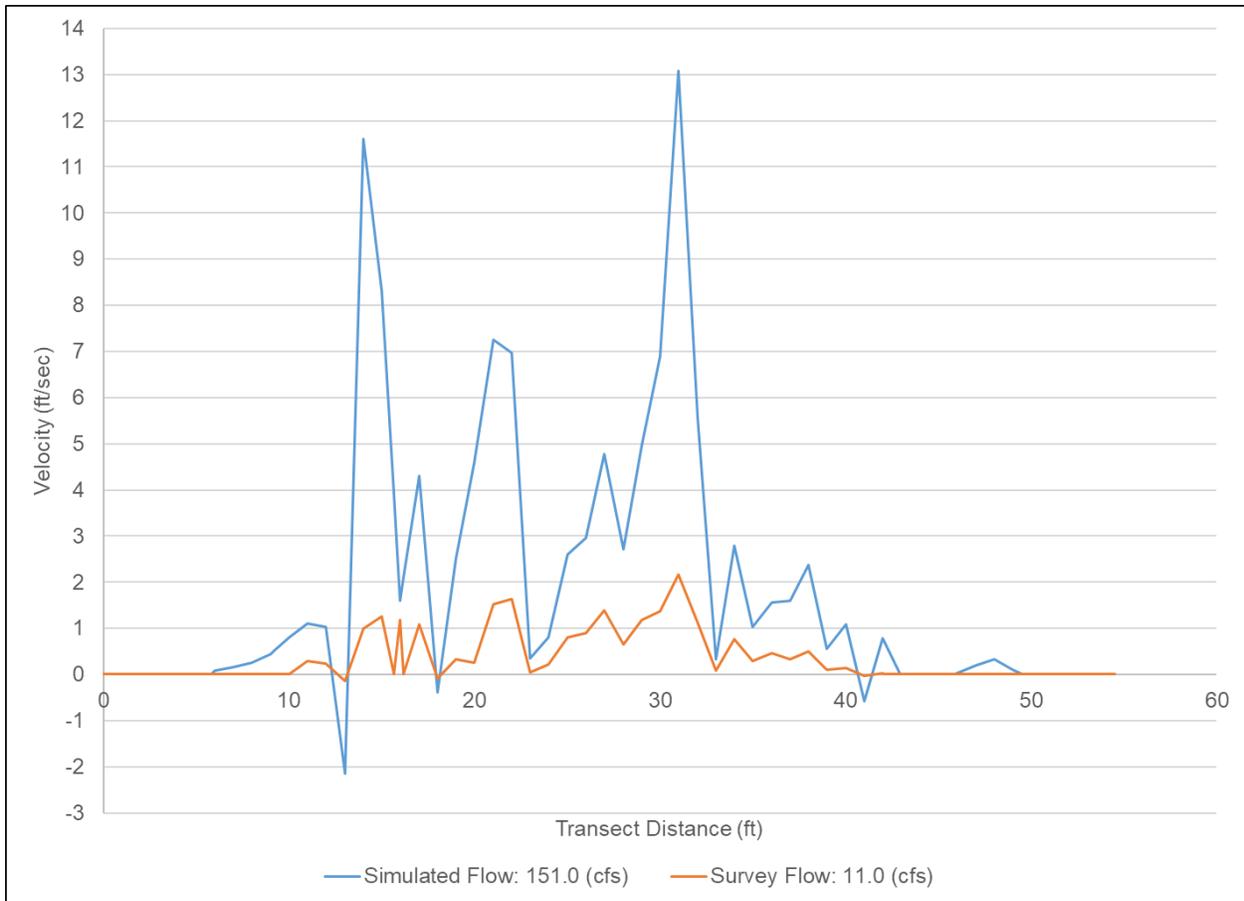

Figure 9. Example simulation of small negative velocities in SEFA. Velocities increase in negative magnitude at higher simulated flow levels.

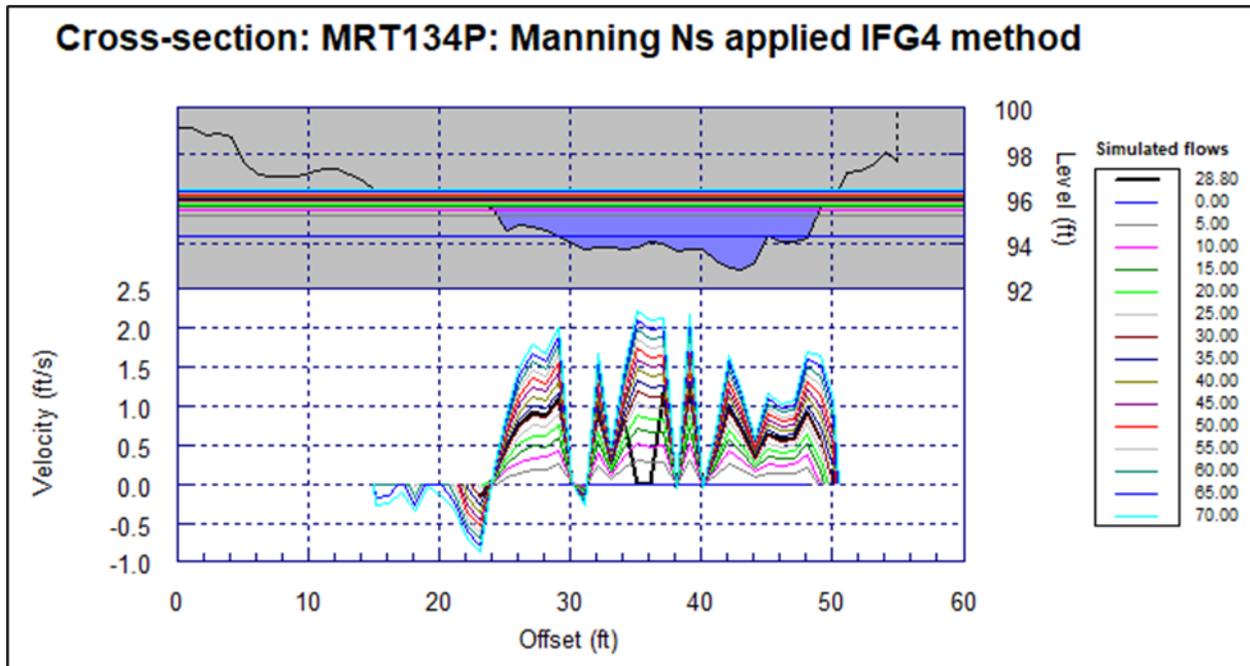

Figure 10. Example transect where the pattern of the simulated velocities does not appear to follow the trend of the field measured velocity profile (bold black line at stations 35 and 36).

3.0 RESULTS

The habitat mapping and model calibration results for the 10 reaches in Redwood Creek are described in the following sections. The specific outputs related to model performance are provided in Appendices B through G.

3.1 Mesohabitat Unit Weighting

Staff completed mesohabitat surveys of all 10 study reaches. The mesohabitat types found to represent more than five percent of the total length of each study reach were identified for site selection. The term ‘weighted’ in AWS refers to the way the contribution of each mesohabitat type is weighted in 1D models by length. The weight of a given mesohabitat type in each reach is proportional to the percentage of the reach that mesohabitat type comprised. Table 15 through Table 24 summarizes the percent by length of each mesohabitat type in each reach, the final number of calibrated transects in each mesohabitat type by reach and resulting transect weights used in SEFA to compute AWS.

Table 15. Lower Redwood Creek transect weighting factors by percent.

Mesohabitat Type	Weight of Mesohabitat Type Sampled (%)	Number of Transects	Transect Weights (%)

3.2 Calibration Discharge

The discharge measurements used to develop the stage-discharge rating for each transect in SEFA are provided in Appendix B. Stage-discharge rating development requires at least three distinct flows be measured. Discharge measurements were taken at locations near the transect to minimize the impact of stream gains and losses between the position of the transect and the discharge measurement. Typically, the discharge measurements were taken at the closest glide unit to the transect unit being surveyed. The positions of the transects are provided in the reach maps, Appendix A.

3.3 Stage-discharge Rating Curve Utility Selection and Calibration

The stage-discharge rating relationship was computed for each transect using two utilities available in SEFA: log-log regression and MANSQ. The hydraulic model utility calibration results are given in Appendix C. These results include the reach calibration results for mean error of predicted versus measured discharge, beta value for either method, and VAF for the selected rating utility. In Appendix C, the mean error of the rating utility selected is indicated in bold. The minimum, maximum, and mean of calibration mean error by reach are summarized in Table 25 through Table 34.

Table 25. Lower Redwood Creek summary of Calibration Mean Error, WSEL Error, Calibration Flow VAF, and Simulation Velocity VAF results.

Parameter	Guidance Range	Min.	Max.	Mean

3.4 WSEL Simulation

The stage-discharge utility selected in SEFA (above) was used to predict WSELs. The field-measured WSELs and the WSELs predicted by SEFA are reported in Appendix D for each transect by reach. All predicted WSELs were within the threshold in the USFWS guidelines for PHABSIM, which recommended a difference of 0.1 ft or less (USFWS 1994) between surveyed and modeled WSEL. The minimum, maximum, and mean difference between measured and predicted WSEL by reach are summarized in Table 25 through Table 34.

3.5 Simulated Flow Range and Velocity Calibration by VAF

The transect velocity profiles collected during the survey flow were imported into SEFA and used to predict velocity profiles over the range of simulated flows. The simulated velocity profiles for each transect are presented in Appendix E for each transect by reach. Appendix F also includes the revised velocity simulated profiles for transects that were subject to VDF modification summarized in Table 35. The VAFs for all the simulated flows were plotted, with discharge on the x-axis and VAF on the y-axis. The discharge/VAF plots for each reach are given in Appendix F.

Velocities for each reach were initially simulated using the recommended range of 0.4 times the lowest measured flow to 2.5 times the highest measured flow (USGS 2001). Depending upon the discharge versus VAF results, the simulation discharge range was limited to meet the recommended VAF ratio for simulated velocity (Thomas R. Payne and Associates 1998). The final simulation range of each reach is indicated in the plots in Appendix F. The minimum, maximum, and mean range of VAFs for the velocities simulated by reach are summarized in Table 25 to Table 34.

Table 35. Adjusted VDFs.

Transect	Offset Distance (ft)	Default VDF	Initial Maximum Simulated Velocity (ft/s)	Revised VDF	Final Maximum Simulated Velocity (ft/s)
LRT88L	13	-0.020	-2.150	-0.050	-0.895
MRT134P	35	0.250	2.259	4.670	0.105
MRT134P	36	0.250	2.133	4.670	0.099
ST33L	31	0.015	3.866	0.191	0.319
ST33L	34	0.059	1.054	0.076	0.870
ST33L	35	0.026	2.387	0.154	0.432
MCT133R	33	-0.180	-1.149	-0.250	-0.796
MCT133R	34	-0.110	-1.289	-0.200	-0.709
LCT32L	8	0.023	3.731	0.079	1.133

3.6 Velocity Distribution Factors

The simulated velocity profiles for each transect were reviewed to determine whether the simulated velocity patterns were consistent with the pattern of the velocity profile measured in the field. Attention was placed on transects containing negative velocities. As discussed in Section 2.4, small negative velocities were present in some of the transects near the stream margins. Two of the 77 transects were found to have negative velocities near the stream margins with negative magnitudes greater than -1 ft/s at the maximum simulation flow. The initial VDF factors were reduced in one cell for transect LRT88L and two cells for MCT113R to minimize extrapolation of negative velocities to -1 ft/s (Table 35).

The other three transects listed in Table 35 possessed simulated velocity patterns that did not appear to be consistent with the pattern measured in the field (see Figure 10). The cross section VDF plots for all five transects before and after modification are presented in Appendix G.

4.0 DISCUSSION

The hydraulic calibration of 1D transects involves applying guidance standards from the literature (Milhous et al. 1989; Thomas R. Payne and Associates 1998; USFWS 1994; USFWS 2011; USGS 2001) to the model outputs to ensure the model performance meets existing standards. In situations where transect outputs do not meet the standards, the transect data are further evaluated. Data were evaluated to determine whether a mistake was made in the data collection or entry process, if the stage-discharge relationship was altered between surveys by a change in the transect lateral or longitudinal profile, or if the transect was a poor candidate for hydraulic modeling in 1D.

Transects were omitted if their hydraulic modeling outputs did not meet the standards given in Table 25 to Table 34. Omitted transects are included in Table 1 to Table 10 and the rationale for each omission is reported in Appendix C.

4.1 Application of *Best SZF* Utility

Two pool habitat units, Middle Redwood Creek reach habitat unit 149 (MRT149P) and Dinner Creek habitat unit 14 (DT14P), did not meet the standard for mean error of 10% using the log-log regression utility. Digital images of the sites taken during the field surveys indicated that large substrates, boulders and/or down tree trunks obscured the actual SZF elevation from view or made placing the stadia rod on the location impossible. In these isolated incidents staff were unable to survey the correct bed elevation for SZF. The pool unit, MRT149P, was dominated by large substrates (Figure 11) obscuring the SZF elevation. In pool unit DT14P (Figure 12) the downstream hydraulic control elevation was obscured by the combination of a large boulder and downed tree trunk. The *Best SZF* utility was used to estimate the SZF for these two pool units.

Figure 11. Large substrates in habitat unit MRT149P.

Figure 12. Surveying SZF flow in habitat unit DT14P.

The *Best SZF* utility is described in detail in the Section 2.4. The utility solves for the SZF that gives the best fit for the hydraulic rating curve. In the absence of a reliable field measurement, the *Best SZF* function optimizes the log-log regression.

4.2 Mean Error Threshold Units

Two transects with mean errors just above the acceptable threshold of 10% were included in the analysis because the transect performance was well within the other standards. In Upper Redwood Creek, the low gradient riffle habitat unit URT43L was included in the analysis even though the MANSQ mean error was 10.095%. The maximum variance of WSEL at any of the stage-discharge pairs was 0.03 ft. The calibration VAF was equal to 0.89, and the range of velocity simulation VAF was 0.459 to 1.347. The glide transect UCT72G in Upper China Creek was included in the analysis with a MANSQ mean error of 10.197%. The maximum variance of WSEL at any of the stage-discharge pairs was 0.04 ft. The calibration VAF was equal to 1.07, and the range of velocity simulation VAF was 0.370 to 1.611.

5.0 CONCLUSION

Department staff developed a series of hydraulic models at selected 1D transects in 10 reaches of the anadromous portion of Redwood Creek including tributaries using the computer program SEFA. This report documents the Department's efforts to collect and compile field data and develop and calibrate those hydraulic models used to compute flow versus habitat relationships. As is described in the report, Department staff followed standard methods while collecting field data and applied standard techniques during model development and calibration.

6.0 ACKNOWLEDGEMENTS

We would like to thank the following Department staff for their assistance with this report: Amber Villalobos, Brionna Drescher, Bronwen Stanford, Danielle Elledge, Diane Haas, Hanna Casares, Jason Hwan, Lanette Richardson, Michael Maher, Mike Hancock, Nicole Gephart, Paige Uttley, and Todd Carlin.

APPENDIX C: SEFA HYDRAULIC MODEL UTILITY CALIBRATION RESULTS

The following notes and definitions explain the equations and quantities used to quantify the hydraulic model utility calibration results for each reach of the Redwood Creek 1D analysis using the program SEFA. The hydraulic model utility selected for simulation of depth and velocity is indicated by the **bolded mean error** and an asterisk (*) in the following tables.

SZF rating (log-log regression): Fitted as best fit to survey stage and flow, rating calibration stages and flows, and stage for zero flow: $\text{Flow} = A \times (\text{Water level} - \text{SZF})^{\text{exp}}$

Where:

Q = flow (cfs)
A = regression coefficient
WSEL = water surface elevation (ft)
SZF = stage of zero flow (ft)
exp = exponential regression coefficient

Best SZF rating (log-log regression using the Best SZF utility): Fitted as best fit to survey stage and flow, rating calibration stages and flows, with best fit stage for zero flow: $\text{Flow} = A \times (\text{Water level} - \text{const})^{\text{exp}}$

Where:

Q = flow (cfs)
A = regression coefficient
WSEL = water surface elevation (ft)
exp = exponential regression coefficient
const = constant

Hydraulic formula (MANSQ): $Q = 1/N \times \text{Area} \times (R - R_{\text{SZF}})^{2/3} \times S^{1/2}$

Where:

Q = flow (cfs)
 $N = A \times Q^{\text{beta}}$
A = regression coefficient
beta = MANSQ exponential regression coefficient
Area = cross-sectional area of the transect (ft²)
R = hydraulic radius (ft)
 R_{SZF} = hydraulic radius at the SZF (ft)

S = slope of the water surface (ft/ft)

- The mean error (%) and coefficient of determination (R²) show the goodness of fit of the rating to the gagings.
- The mean error is the mean percentage error in predicted and rating calibration discharges as a % of the rating calibration discharges.
- The coefficient of determination is derived by comparing measured and predicted stages.
- $R^2 = 1 - \text{Residual sum of squares} / \text{Total sum of squares}$
- $\text{Residual sum of squares} = \text{Sum} ((\text{Measured stage} - \text{predicted stage})^2)$
- $\text{Total sum of squares} = \text{Sum} (\text{Measured stage}^2) - (\text{Sum} (\text{Measured stage}))^2 / \text{Number of points on rating}$
- Ratings are fitted by the least-squares geometric mean method to x and y deviations as described in the manual.

Table C-1. Lower Redwood Creek SEFA outputs comparing SZF rating (log-log regression) with hydraulic rating (MANSQ) by transect. An asterisk (*) by the bolded mean error signifies which WSEL/flow rating utility was chosen, log-log regression or MANSQ.

^a SZF rating utility was chosen because the WSELs predicted by the hydraulic rating did not meet the 0.1 threshold when compared to the field measured WSELs.

^b *Best SZF* utility was used to predict simulated stage-discharges.

^c Omitted because the calibration did not meet the standard for mean error.

^d Omitted because the calibration did not meet the guidance standard for mean error with log-log regression and did not meet the calibration standard for VAF when the *Best SZF* utility was applied. *Best SZF* utility was used to predict simulated stage-discharges.

Table C-3. Upper Redwood Creek SEFA outputs comparing SZF rating (log-log regression) with hydraulic rating (MANSQ) by transect. An asterisk (*) by the bolded mean error signifies which WSEL/flow rating utility was chosen, log-log regression or MANSQ.

^x Omitted because the magnitude of the gage VDFs were beyond the guidance limits.

^y Best SZF utility was used to predict simulated stage-discharges.

^z Omitted because the calibration did not meet the standard for mean error.

^{aa} Omitted because the calibration VAF exceeded the standard of 1.25.

^{bb} Omitted because the calibration did not meet the standard for mean error.

APPENDIX D: CALIBRATION FLOWS AND WATER SURFACE ELEVATIONS

The maximum allowable variance between measured and predicted WSELs was 0.1 ft. Transects that failed the WSEL standard are indicated by strikethrough in the tables. Transects that met the WSEL standard but failed the Calibration VAF standard or the VAF velocity simulation standard are also indicated by strikethrough and were subsequently omitted.

Table D-1. Lower Redwood Creek calibration flows and WSELs for each transect.

APPENDIX E: TRANSECT VELOCITY PROFILES

The following figures present the predicted discharge-WSEL pairs and velocity profiles for each transect. The predicted discharge-WSEL pairs and velocity profiles were plotted over a range of flows. Each of the figures contains a layered plot with the transect length coordinates (Offset (ft)) on the x-axis, water level (ft) on the upper y-axis, and velocity (ft/s) on the lower y-axis. The thicker black lines represent the survey flow (the reference discharge-WSEL pair) used to predict WSEL and velocity within SEFA. The upper half of each figure shows the transect profile with a horizontal line representing the water level of each simulated flow, including the survey flow. The filled-in blue area represents water below the survey flow. The lower half of each figure is the velocity profile for each flow simulated to compute AWS, including the survey flow (thicker black line). Please refer to Section 2.3.5 *Discharge Simulation Range* and Section 2.3.6 *Water Velocity Prediction* for further details about discharge-WSEL and velocity prediction.

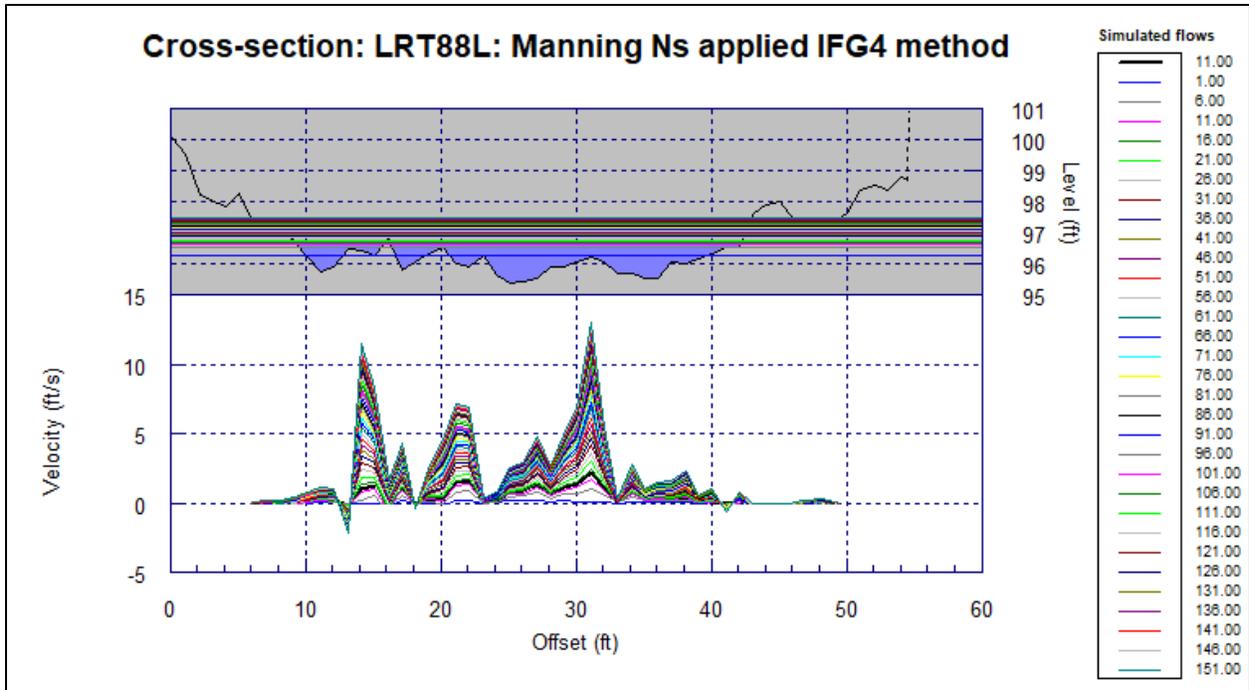

Figure E-1. Lower Redwood Creek cross-section LRT88L before VDF modification at simulated flows ranging from 1 cfs to 151 cfs.

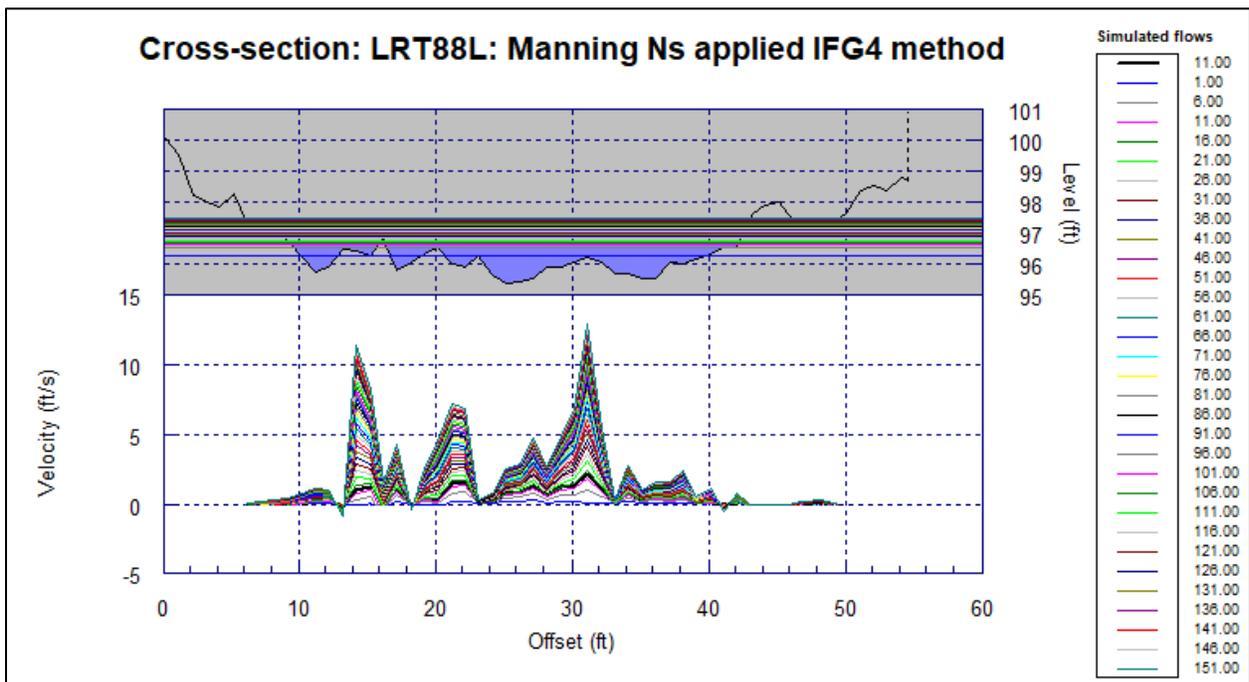

Figure E-2. Lower Redwood Creek cross-section LRT88L after VDF modification at simulated flows ranging from 1 cfs to 151 cfs.

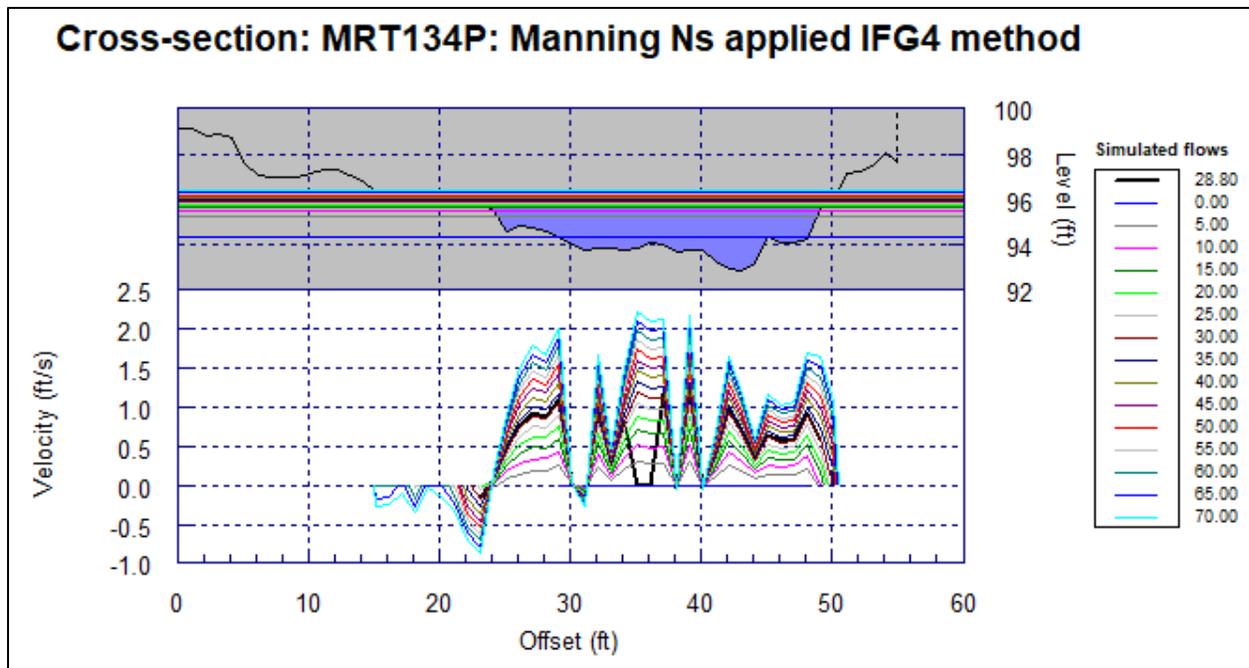

Figure E-3. Middle Redwood Creek cross-section MRT134P before VDF modification at simulated flows ranging from 0 cfs to 70 cfs.

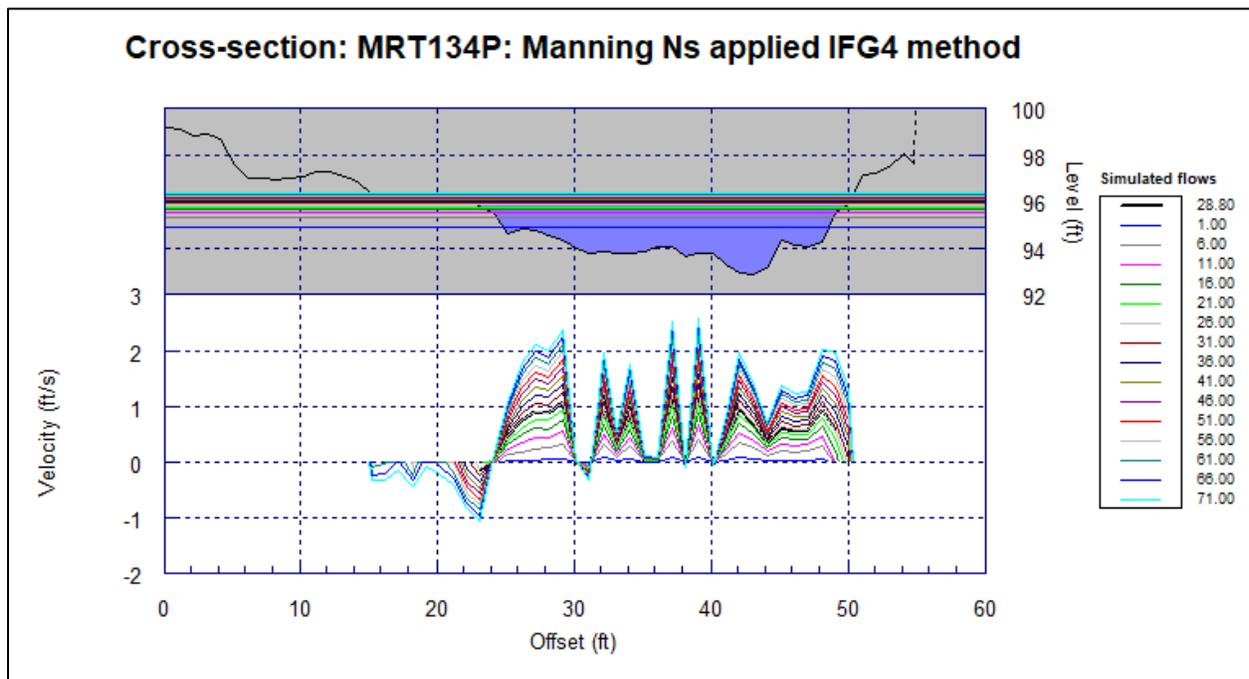

Figure E-4. Middle Redwood Creek cross-section MRT134P after VDF modification at simulated flows ranging from 1 cfs to 71 cfs.

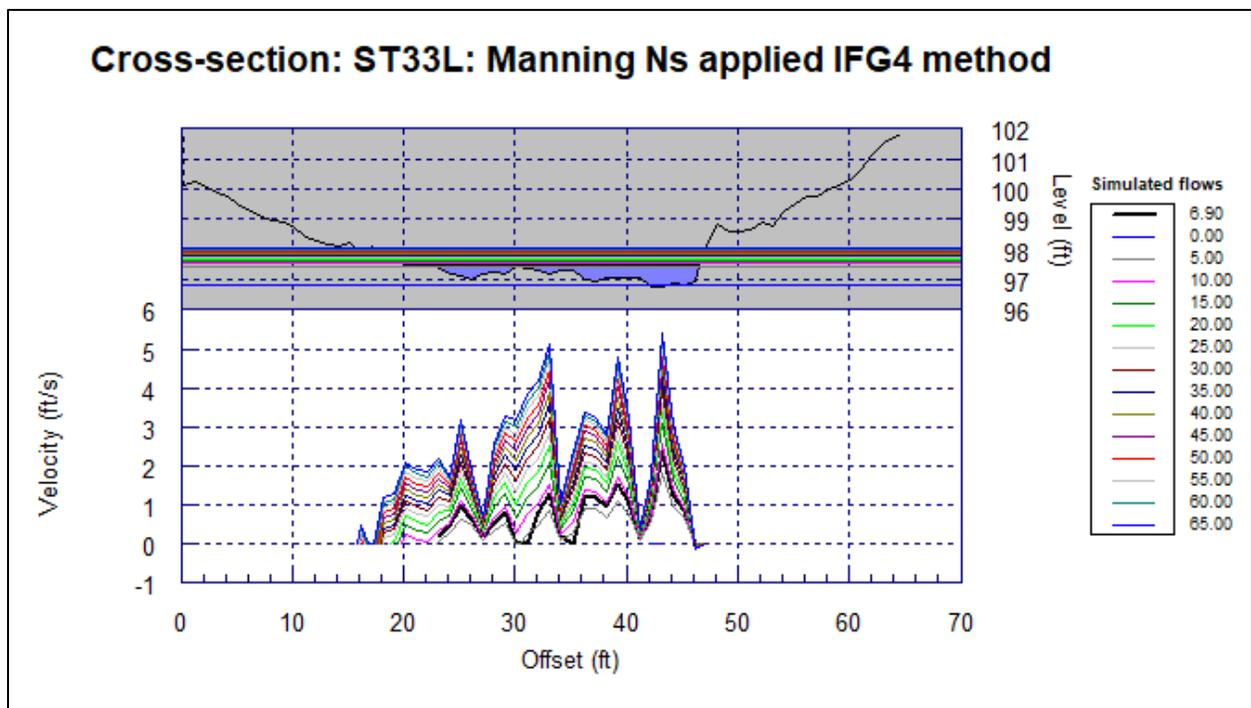

Figure E-5. Seely Creek cross-section ST33L before VDF modification at simulated flows ranging from 0 cfs to 65 cfs.

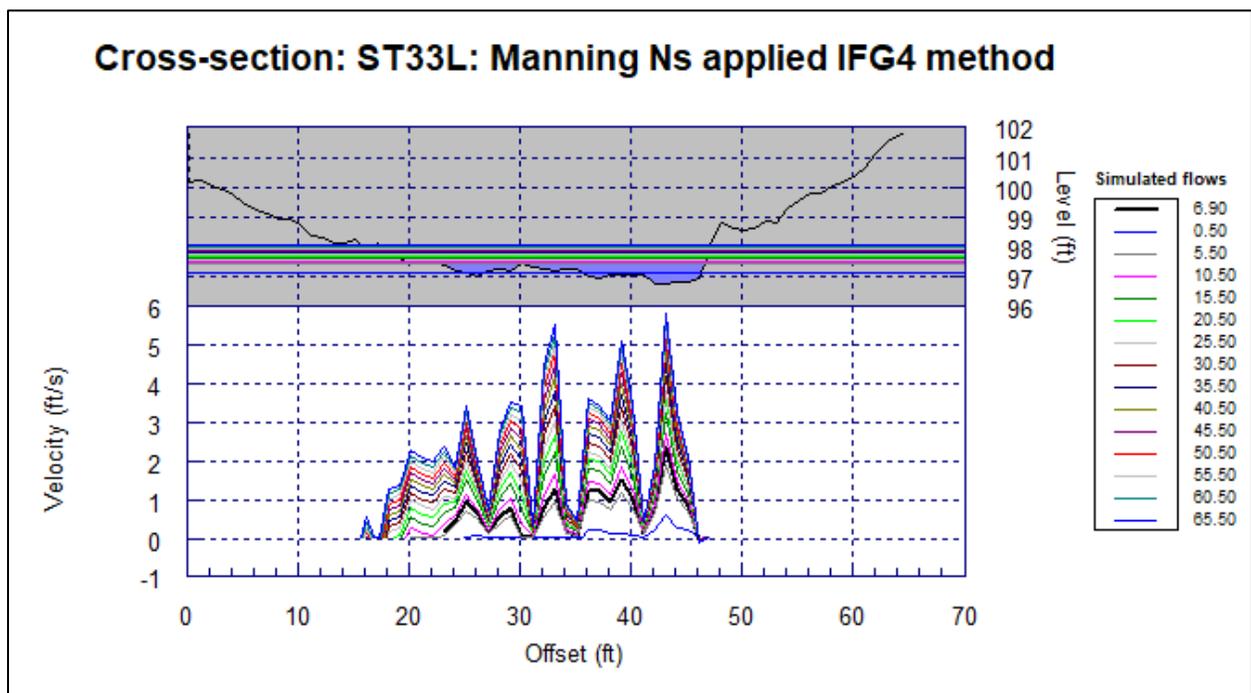

Figure E-6. Seely Creek cross-section ST33L after VDF modification at simulated flows ranging from 0.5 cfs to 65.5 cfs.

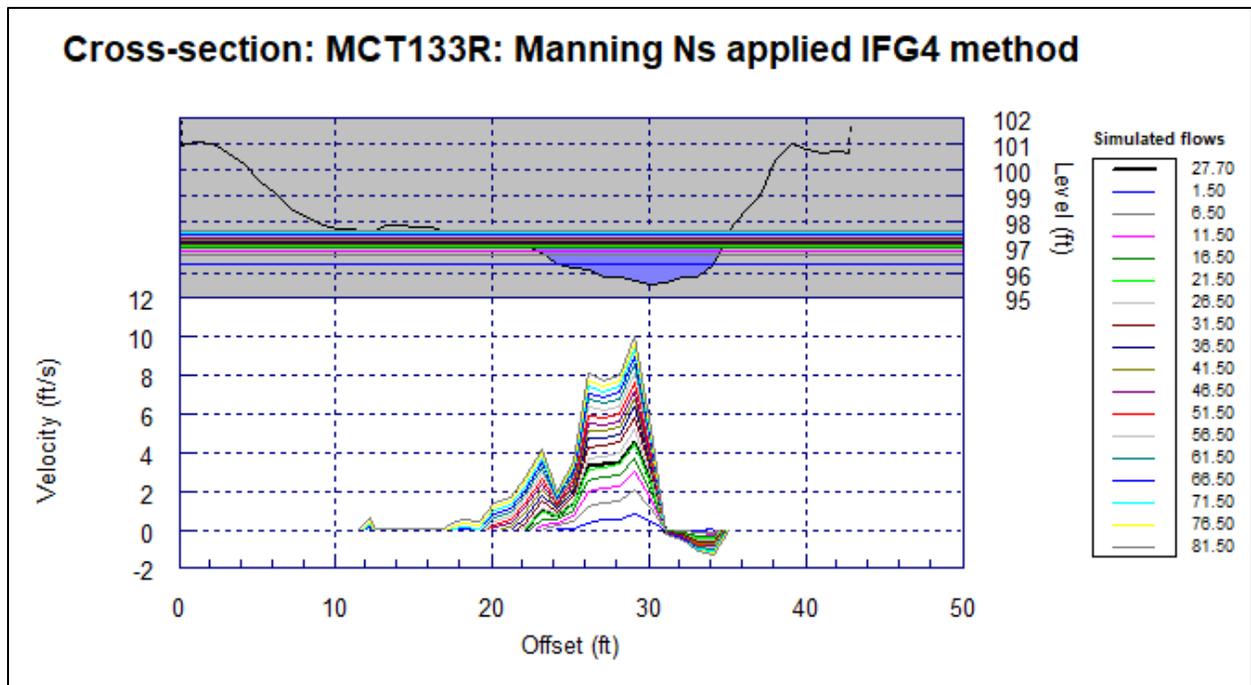

Figure E-7. Miller Creek cross-section MCT133R before VDF modification at simulated flows ranging from 1.5 cfs to 81.5 cfs.

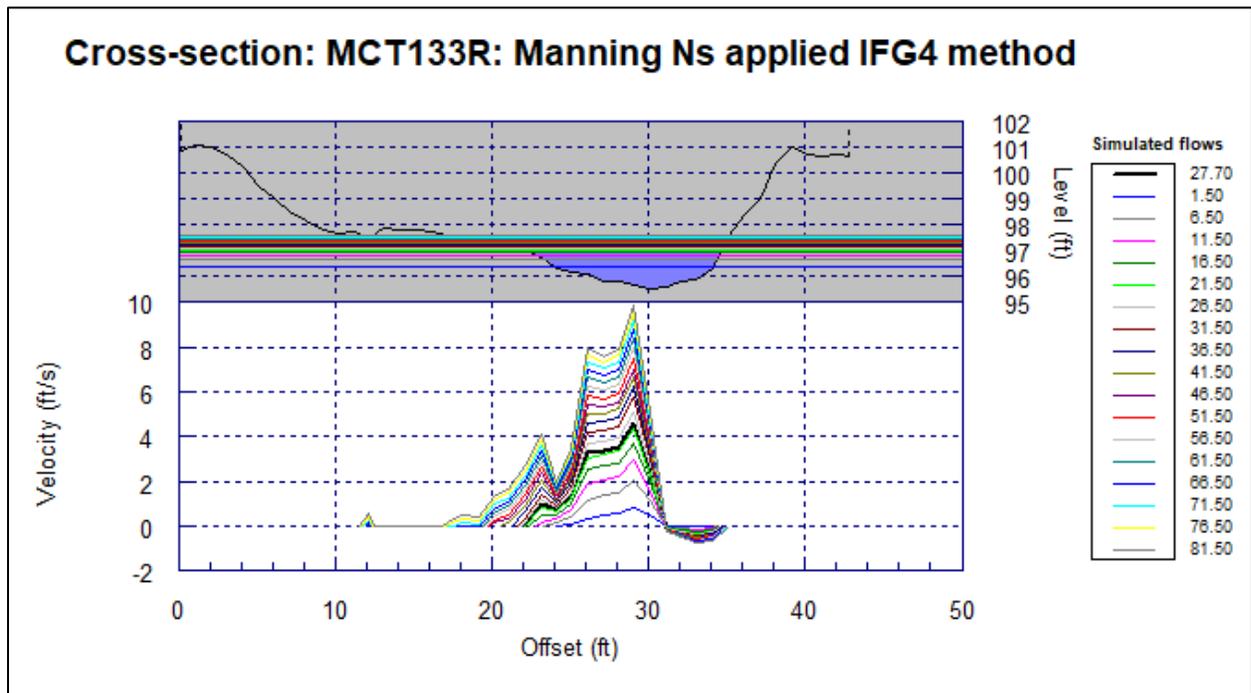

Figure E-8. Miller Creek cross-section MCT133R after VDF modification at simulated flows ranging from 1.5 cfs to 81.5 cfs.

APPENDIX F: VELOCITY SIMULATION VELOCITY ADJUSTMENT FACTORS

The standard variance for velocity simulation VAFs is 0.1 to 5.0. The results for each reach were plotted, with discharge on the x-axis and VAF on the y-axis. The range of simulated flows was modified slightly from 0.4 times the lowest measured reach discharge to 2.5 times the highest measured reach discharge to ensure that velocity simulation VAF fell within the guidance standard.

APPENDIX G: SELECTED VELOCITY DISTRIBUTION FACTOR PROFILES

This appendix presents the graphical Velocity Distribution Factor (VDF) results for modifications made to six of the total 75 transects used to estimate flow-habitat relationships in Redwood Creek. VDFs were only modified to improve velocity profile prediction or to minimize the exaggeration of negative velocities measured near stream margins.

Each of the figures contains a layered plot with the transect length coordinates (Offset (ft)) on the x-axis, water level (ft) and velocity on the upper y-axis, and the Manning N value or VDF for each transect velocity profile point on the lower y-axis. The upper plot shows the transect and velocity profiles. The survey flow water level is indicated by a solid blue fill. The lower plot is the profile of the unmodified Manning N value or VDF, for the transect being evaluated.
